Between 1<sup>st</sup> and 2<sup>nd</sup> April 2010 a team from the Italian Istituto Nazionale di Geofisica e Vulcanologia working in collaboration with the scientists from Institute of Earth Sciences, University of Iceland conducted remote sensing gas measurements on eruptive fissures at Fimmvörðuháls. Three measurement techniques were applied: open-path FTIR, DOAS and an SO<sub>2</sub> imaging system. The FTIR spectrometer uses infrared radiation emitted from the erupting lavas as a radiation source for absorption spectrometry of volcanic gases emitted from the explosive vents. Spectra are analysed using a single-beam retrieval which allows path amounts of H<sub>2</sub>O, CO<sub>2</sub>, SO<sub>2</sub>, HCl and HF to be determined. Favourable wind conditions allowed traverse measurements under the gas plume emitted from the eruption to be conducted with a DOAS spectrometer, allowing the flux of SO<sub>2</sub> to be determined. The SO<sub>2</sub> imaging camera was used to measure the individual gas emissions from the erupting fissures. Combining these measurements together we can report the following preliminary observations for 1<sup>st</sup> and 2<sup>nd</sup> April:

- The SO<sub>2</sub> gas flux produced by the eruption was ~3000 tonnes per day.
- Approximately 70% of the SO<sub>2</sub> flux was produced by the fissure which opened on 31<sup>st</sup> March, with ~30% emitted from the 21<sup>st</sup> March fissure.
- The flux of HF from the eruption was ~30 tonnes per day.
- Gas compositions emitted from the two eruption fissures were broadly similar, being very rich in H<sub>2</sub>O (>80% by mole), <15 % CO<sub>2</sub> and <3% SO<sub>2</sub>.
- Strong variations between 5 and 25 in the SO<sub>2</sub>/HCl ratio were observed at the 31<sup>st</sup> March fissure on the two measurement days, with higher values observed on 1<sup>st</sup> April when the activity was apparently more intense than 2<sup>nd</sup> April.
